# One-step solvothermal preparation of Fe<sub>3</sub>O<sub>4</sub>/graphene composites at elevated temperature and their application as anode materials for lithium-ion batteries

Laiying Jing,<sup>a</sup> Aiping Fu,<sup>a</sup> Hongliang Li,<sup>\*a</sup> Jingquan Liu,<sup>a</sup> Peizhi Guo,<sup>\*a</sup> Yiqian Wang<sup>b</sup> and Xiu Song Zhao<sup>ac</sup>

A one-step high-temperature solvothermal process (can be used up to 400 °C) has been explored for the preparation of Fe<sub>3</sub>O<sub>4</sub>/graphene composites. The influence of high temperature (>230 °C) on the structure, morphology and electrochemical properties of the resulting Fe<sub>3</sub>O<sub>4</sub>/graphene composites was investigated by XRD, SEM, TEM and N<sub>2</sub> adsorption–desorption measurements. Electrochemical performances of the as-prepared Fe<sub>3</sub>O<sub>4</sub>/graphene composites at different temperatures were evaluated in coin-type cells as anode materials for lithium-ion batteries. In comparison with the traditional solvothermal method (<240 °C), the high-temperature method does not require an additional calcination process yet it still could result in Fe<sub>3</sub>O<sub>4</sub>/graphene composites with pure phase and excellent electrochemical properties. A preferred solvothermal temperature of 280 °C has been deduced based on a series of control experiments. The Fe<sub>3</sub>O<sub>4</sub>/graphene composite derived at 280 °C exhibited a high reversible capacity of 907 mA h g<sup>−1</sup> at 0.1 C (92.6 mA g<sup>−1</sup>) even after 65 cycles, showing outstanding cycle stability. It also exhibited a high rate capability of 410 mA h g<sup>−1</sup> at 2 C (1852 mA g<sup>−1</sup>). The role of the graphene substrates in improving the electrochemical properties of the composite is discussed based on the morphology, structure, phase and electrochemical property studies.

## 1. Introduction

Recently, lithium-ion batteries (LIBs) have generated great interest because of the impact of portable electronic devices. Transition metal oxides have been considered as promising high-performance anode materials for LIBs due to their high energy density, safety for diverse applications, environmental friendliness and low cost.<sup>1–6</sup> Among the transition metal oxides, magnetite (Fe<sub>3</sub>O<sub>4</sub>) is the most promising candidate anode material for LIBs because of its higher theoretical reversible capacity (926 mA h g<sup>−1</sup>) in comparison with carbonaceous substances.<sup>7–10</sup> However, the low initial coulombic efficiency and the severe volume changes during the Li ion insertion/extraction processes lead to a poor cycling performance, limiting the commercialization of this potential material.<sup>11–14</sup> Hence, a flexible strategy for improving the reversible capacity

and long-cycle performance has been of significant interest in developing high-performance LiB anode materials. Graphene is a one-atom thick planar sheet in a honeycomb crystal lattice and has been extensively explored as conductive materials for energy storage.<sup>15,16</sup> Graphene/Fe<sub>3</sub>O<sub>4</sub> composites with excellent LIB performance have also been reported.<sup>17–19</sup> Graphene shows three main advantages as conductive substrates for the fabrication of composite electrode materials. Firstly, the sheets can provide voids against the volume changes of the Fe<sub>3</sub>O<sub>4</sub> particles during the Li ion insertion/extraction processes.<sup>20–22</sup> Secondly, graphene sheets can prevent the aggregation of Fe<sub>3</sub>O<sub>4</sub> particles by the lamellar structure. Thirdly, it also can improve the rate performance of the composites due to its intrinsic high electronic conductivity. In the previous studies, most of the graphene/Fe<sub>3</sub>O<sub>4</sub> composites were prepared by hydrothermal or solvothermal methods at a temperature below 200 °C due to the limitation of the Teflon liner (the softening point of the polytetrafluoroethylene autoclave liner is 240 °C). Usually, the normal solvothermal process necessitates a long reaction time (more than 12 h and even several days) and requires a subsequent calcination step at temperatures higher than 500 °C to obtain transition metal oxide based composite materials with pure phase and excellent electrochemical properties.<sup>23–25</sup> One question then arises: what will happen when the solvothermal

preparation of transition metal oxide is conducted at a temperature higher than 240 °C? However, it is difficult to find an answer in the literature due to the temperature limitation of normal structured autoclaves.

Attempting to address the above question and to exploit new techniques, a one-step high-temperature solvothermal approach (up to 310 °C) for the preparation of Fe<sub>3</sub>O<sub>4</sub>/graphene composites has been explored herein based on a Swagelok structured autoclave using an organic iron(II) compound as precursor. Fe<sub>3</sub>O<sub>4</sub>/graphene composites with high reversible capacity and outstanding cycle stability have been prepared within 6 h *via* this high-temperature solvothermal process and no further calcinations were needed. The influence of treatment temperature and reaction time on the composition, structure, morphology and electrochemical properties of the resultant Fe<sub>3</sub>O<sub>4</sub>/graphene composites were investigated in detail.

## 2. Experimental section

### 2.1. Materials

Ferrous oxalate dihydrate, ferric chloride hexahydrate, anhydrous sodium acetate and ethylene glycol (Sinopharm Chemical Reagent Co., Ltd) were of AR grade and used without further purification. Graphene, kindly provided by the sixth element (Changzhou) Ltd, was used as received without further treatment.

### 2.2. Synthesis of Fe<sub>3</sub>O<sub>4</sub>/graphene composites

The Fe<sub>3</sub>O<sub>4</sub>/graphene composites were synthesized by a simple one-step high-temperature solvothermal process. Typically, 0.32 g of ferrous oxalate dihydrate, 0.2 g of anhydrous sodium acetate and 0.011 g of graphene were added to 5 mL of ethylene glycol under vigorous stirring. After stirring for 20 min, the mixture was transferred into a Swagelok structured stainless autoclave with a capacity of 8 mL (a homemade stainless steel (316) high-pressure cell with a Swagelok fitting was used to maintain the pressure at high temperatures up to 400 °C). Then the autoclave was put into a thermostatic oven for solvothermal treatment for 6 or 12 h at different temperatures (210, 230, 250, 280 or 310 °C). After the autoclave had cooled down to room temperature naturally, black precipitates were collected after centrifugation. The solids were washed with distilled water and ethanol twice, respectively, and then dried at 60 °C in a thermostatic oven, obtaining about 0.12 g Fe<sub>3</sub>O<sub>4</sub>/graphene composite with a reproducible yield of 85% calculated based on ferrous oxalate dihydrate. The resultant composites prepared under different temperatures were designated as Fe<sub>3</sub>O<sub>4</sub>/graphene (*T* °C) in the following discussion (where *T* = 210, 230, 250, 280 or 310 °C, respectively, corresponding to the applied treating temperatures). An illustration of the formation process of the Fe<sub>3</sub>O<sub>4</sub>/graphene composites is illustrated in Scheme 1. For comparison purposes, Fe<sub>3</sub>O<sub>4</sub> nanoparticles were prepared in the same way as that of Fe<sub>3</sub>O<sub>4</sub>/graphene but in the absence of graphene. As a control experiment, the Fe<sub>3</sub>O<sub>4</sub>/graphene composite was also prepared using the traditional solvothermal

Scheme 1 Illustration of the formation process of the Fe<sub>3</sub>O<sub>4</sub>/graphene composites.

method at 200 °C for 12 h using ferric chloride hexahydrate as precursor.<sup>26</sup>

### 2.3. Characterization

The crystallographic information and composition of the products were investigated using a Bruker D8 advance X-ray diffractometer (XRD, Cu-K $\alpha$  radiation  $\lambda$  = 0.15418). Fourier transform infrared spectra were recorded from 400 to 4000 cm<sup>-1</sup> with a Nicolet 5700 spectrophotometer using pressed KBr pellets. Raman spectra were collected using a Horiba LabRAM HR Raman spectrometer (HORIBA Jobin Yvon Ltd.). The carbon content in the composites was determined by thermogravimetric analysis under an oxygen atmosphere with a heating rate of 10 °C min<sup>-1</sup> (Mettler Toledo TGA/STDA851<sup>o</sup>). The morphologies and the structures of the samples were examined by a JEOL JSM-6390LV scanning electron microscope (SEM) and a JEOL JEM-2010F transmission electron microscope (TEM). The specific surface areas were estimated with the Brunauer–Emmett–Teller (BET) method with N<sub>2</sub> adsorption data in the relative pressure range of  $P/P_0$  = 0.05–0.35. The pore size distributions were calculated using the Barrett–Joyner–Halenda (BJH) model applied to the desorption branch of the N<sub>2</sub> isotherms obtained with a TriStar 3000 surface area and pore analyzer (Micromeritics).

### 2.4. Electrochemical testing

The working electrodes were prepared by mixing the active material, acetylene black (super-P) and polyvinylidene fluoride

EC : DMC : EMC volume ratio of 1 : 1 : 1 (Tianjin Jinniu Power Sources Material Co., LTD) as the electrolyte. Pure lithium foil was used as counter electrode. The charge–discharge tests were carried out on a LAND Cell Test System (2001A, Wuhan, China) between cutoff voltages of 3 V and 0.01 V. Cyclic voltammetry (CV) tests in two electrode coin-type cells were performed between 0.01 V and 3 V at a scan rate of 0.1  $\text{mV s}^{-1}$  on a CHI760D electrochemical working station. Electrochemical impedance spectroscopy (EIS) patterns were recorded using a CHI760D electrochemical working station in the frequency range 100 kHz to 0.01 Hz with an amplitude of 5 mV.

Fig. 7 The nitrogen adsorption–desorption isotherms and BJH pore size distribution curves (inset) of (a)  $\text{Fe}_3\text{O}_4$ /graphene ( $280^\circ\text{C}$ ) composite, (b)  $\text{Fe}_3\text{O}_4$ /graphene ( $230^\circ\text{C}$ ) composite, and (c)  $\text{Fe}_3\text{O}_4$  nanoparticles ( $280^\circ\text{C}$ ).

### 3. Results and discussion

#### 3.1. XRD

Fig. 1 shows the XRD patterns of the as-prepared  $\text{Fe}_3\text{O}_4$ /graphene composites and pristine  $\text{Fe}_3\text{O}_4$  nanoparticles derived from the high-temperature solvothermal process with different treatment times. From the patterns one can see that the sample obtained at a treatment temperature of  $210^\circ\text{C}$  for 12 h did not show the characteristic peaks of  $\text{Fe}_3\text{O}_4$ , indicating no crystalline  $\text{Fe}_3\text{O}_4$  formed or that the formed  $\text{Fe}_3\text{O}_4$  particles were too small to detect. When the temperature was increased higher than  $230^\circ\text{C}$ , the XRD patterns of the resultant  $\text{Fe}_3\text{O}_4$ /graphene composite and the control  $\text{Fe}_3\text{O}_4$  nanoparticles are in good agreement with crystalline  $\text{Fe}_3\text{O}_4$  (JCPDS, no. 19-0629). The reaction time can even be shortened to 6 h at a treatment temperature of  $280^\circ\text{C}$ . No obvious diffraction peaks of graphene in the  $\text{Fe}_3\text{O}_4$ /graphene composite can be observed, indicating that the stacking of graphene sheets is disordered in these composites.<sup>27</sup>

#### 3.2. FTIR spectra

Fig. 2 shows the FTIR spectra of the as-prepared  $\text{Fe}_3\text{O}_4$  nanoparticles and  $\text{Fe}_3\text{O}_4$ /graphene composites measured in the wavelength range of  $400\text{--}4000\text{ cm}^{-1}$ . The absorption band around  $586\text{ cm}^{-1}$  can be assigned to Fe–O stretching vibration modes. The peak at  $1108\text{ cm}^{-1}$  can be attributed to the skeletal C–O stretching vibration. The peak at  $1620\text{ cm}^{-1}$  can be assigned to C=C bending vibrations of graphene. The weak peak located at  $2918\text{ cm}^{-1}$  was ascribed to the C–H stretching vibration. The wide peak around  $3440\text{ cm}^{-1}$  was assigned to the

stretching vibration of O–H of the adsorbed  $\text{H}_2\text{O}$ . The additional peaks in curve D come from the unreacted precursors of ferrous oxalate dehydrate. This result revealed the coexistence of  $\text{Fe}_3\text{O}_4$  and graphene in the composites and indicated also that a treatment temperature of  $230^\circ\text{C}$  and a reaction time of 12 h are not enough for a complete conversion of the precursor to product.<sup>28,29</sup>

#### 3.3. SEM and TEM measurements

The SEM images of graphene sheets,  $\text{Fe}_3\text{O}_4$  nanoparticles and  $\text{Fe}_3\text{O}_4$ /graphene composites prepared at different temperatures are presented in Fig. 3. From the images it can be seen that the graphene substrate shows a stacked and crumpled morphology (Fig. 3A).<sup>30</sup> Interestingly, the  $\text{Fe}_3\text{O}_4$  nanoparticles prepared solvothermally at  $230^\circ\text{C}$  show a rod-like morphology with lengths of about 2 micrometers and a diameter of about 300 nm (Fig. 3B). On increasing the treatment temperature to  $250^\circ\text{C}$ , was observed that the morphology of  $\text{Fe}_3\text{O}_4$  turned into nanoparticles but mixed with a small amount of rod-like particles (Fig. 3C). At a treatment temperature of  $280^\circ\text{C}$ , the resultant  $\text{Fe}_3\text{O}_4$  particles showed only spherical morphology with diameters in the range of 30–50 nm (Fig. 3D). The comparison reveals that the morphology of the  $\text{Fe}_3\text{O}_4$  products changed gradually from a rod-like structure to spherical particles with increasing of treatment temperature, while the particle sizes decreased. Fig. 3E shows the SEM images of the  $\text{Fe}_3\text{O}_4$ /graphene composite prepared solvothermally at  $280^\circ\text{C}$ . From the SEM image it can be seen that the surface of graphene sheets was decorated tightly with  $\text{Fe}_3\text{O}_4$  nanoparticles. For comparison, Fig. 3F gives a

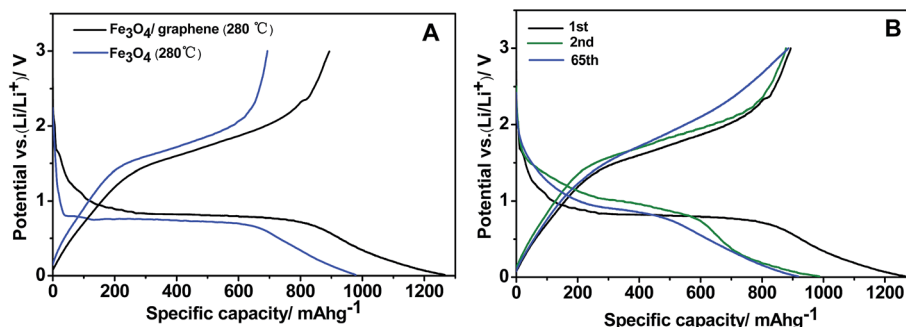

Fig. 8 (A) The first discharge–charge profiles of  $\text{Fe}_3\text{O}_4$ /graphene ( $280^\circ\text{C}$ ) composite and that of  $\text{Fe}_3\text{O}_4$  nanoparticles ( $280^\circ\text{C}$ ) at a current of 0.1 C, (B) The 1<sup>st</sup>, 2<sup>nd</sup> and 65<sup>th</sup> discharge–charge profiles of  $\text{Fe}_3\text{O}_4$ /graphene ( $280^\circ\text{C}$ ) composite at a current of 0.1 C.

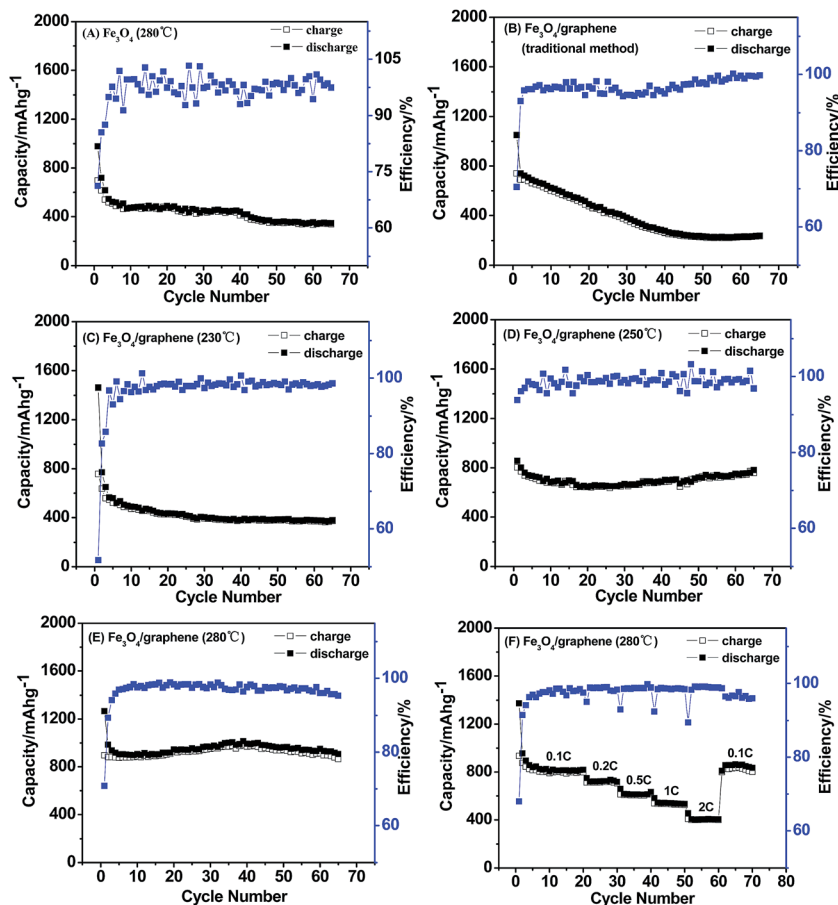

Fig. 9 Specific capabilities of different samples at a current of 0.1 C, (A)  $\text{Fe}_3\text{O}_4$  nanoparticles (280 °C), (B)  $\text{Fe}_3\text{O}_4$ /graphene composite (traditional hydrothermal method), (C)  $\text{Fe}_3\text{O}_4$ /graphene (230 °C) composite, (D)  $\text{Fe}_3\text{O}_4$ /graphene composite (250 °C), (E)  $\text{Fe}_3\text{O}_4$ /graphene (280 °C), and (F) specific capabilities of  $\text{Fe}_3\text{O}_4$ /graphene (280 °C) composite at currents between 0.1–2 C.

SEM image of the  $\text{Fe}_3\text{O}_4$ /graphene composite prepared by the conventional solvothermal method, where a Teflon lined normal autoclave was used for the preparation and 200 °C was set as the maximum treatment temperature. From the SEM image it can be seen that  $\text{Fe}_3\text{O}_4$  particles with diameter of about 250 nm are stacked on the surface of the graphene sheets. In comparison with the traditional solvothermal method, the high-temperature one can result in particles with smaller sizes, which will then lead to a high specific surface area (see Section 3.6) and better electrochemical properties (see Section 3.7).

Fig. 4 shows the TEM image of pristine graphene substrate (A) and that of the  $\text{Fe}_3\text{O}_4$ /graphene (280 °C) composite (B). The image of the graphene substrate shows clearly the layered structure with a stacked and crumpled morphology. The TEM image of the  $\text{Fe}_3\text{O}_4$ /graphene (280 °C) composite confirmed that  $\text{Fe}_3\text{O}_4$  nanoparticles with diameter in the range of 30–50 nm were anchored on the surface of graphene sheets after the solvothermal treatment at 280 °C, which is consistent with the SEM results. The TEM image also revealed that the designed

Fig. 10 AC impedance plots of (A)  $\text{Fe}_3\text{O}_4$ /graphene (280 °C) composite and (B)  $\text{Fe}_3\text{O}_4$  nanoparticles (280 °C).

Fig. 11 Cyclic voltammograms (CV) of  $\text{Fe}_3\text{O}_4$ /graphene ( $280^\circ\text{C}$ ) composite (A) and  $\text{Fe}_3\text{O}_4$  nanoparticles ( $280^\circ\text{C}$ ) (B).

structure can prevent the aggregation of  $\text{Fe}_3\text{O}_4$  nanoparticles effectively.<sup>31–34</sup>

### 3.4. Raman spectra

Curves A and B in Fig. 5 exhibit the Raman spectra of pristine graphene substrate and that of the  $\text{Fe}_3\text{O}_4$ /graphene ( $280^\circ\text{C}$ ) composite, respectively. The two peaks at  $1332$  and  $1561\text{ cm}^{-1}$  in curve A can be assigned to the D and G bands for carbon.<sup>35,36</sup> The G band corresponds to  $\text{sp}^2$  hybridized carbon, while the D band can be attributed to the presence of  $\text{sp}^3$  defects within the carbon. Curve B also possesses D and G bands with peaks at  $1334$  and  $1575\text{ cm}^{-1}$ , respectively. For the  $\text{Fe}_3\text{O}_4$ /graphene composites, the intensity ratio of the D to G bands ( $I_D : I_G$ ) was calculated to be 1.004, which is higher than that of the pristine graphene substrate (0.926). The change of intensity ratio of the D and G bands could be ascribed to the exfoliation of graphene and the presence of  $\text{Fe}_3\text{O}_4$  nanoparticles between graphene sheets.<sup>37,38</sup>

### 3.5. Thermal analysis

Fig. 6 shows the typical TGA profiles of the as-prepared  $\text{Fe}_3\text{O}_4$ /graphene composite,  $\text{Fe}_3\text{O}_4$  particles and pristine graphene, respectively. For the  $\text{Fe}_3\text{O}_4$ /graphene composite, the weight loss of 0.7% between room temperature and  $200^\circ\text{C}$  can be attributed to the loss of adsorbed water. The weight gain between  $200$  to  $450^\circ\text{C}$  was caused by the oxidation of  $\text{Fe}_3\text{O}_4$ . For pure  $\text{Fe}_3\text{O}_4$ , a weight gain of 5.0% was detected, which is close to the theoretical calculation of 3.5%. The pristine graphene showed a drastic weight loss between  $480$  and  $550^\circ\text{C}$ , while the  $\text{Fe}_3\text{O}_4$ /graphene composite presented an obvious weight loss in the range of  $560$  to  $660^\circ\text{C}$ . The variation of temperature range of weight loss for pristine graphene and  $\text{Fe}_3\text{O}_4$ /graphene composite can be explained by the  $\text{Fe}_3\text{O}_4$  anchored tightly onto the surface of the graphene layers retarding the oxidation rate of the graphene substrate. The weight percentages of carbon and  $\text{Fe}_3\text{O}_4$  in the  $\text{Fe}_3\text{O}_4$ /graphene composite were approximately 12.9% and 87.1% as derived from the weight losses of graphene and the mass gains of the oxidation of  $\text{Fe}_3\text{O}_4$ – $\text{Fe}_2\text{O}_3$ . Theoretical contents of 7.4% and 92.6%, respectively, for graphene and  $\text{Fe}_3\text{O}_4$  can be deduced based on the quantity of the applied precursors. The detected carbon content in the composite based on the TGA results is a little bit higher than the theoretical value. The difference between them can be attributed to the

composition character of the  $\text{Fe}(\text{II})$  oxalate precursor, which could introduce *in situ* amorphous carbon to the composites *via* decomposition of the oxalate moieties during the high temperature solvothermal treatment.

### 3.6. Nitrogen adsorption–desorption measurements

$\text{N}_2$  adsorption–desorption isotherms were employed to investigate specific surface area and porosity of the  $\text{Fe}_3\text{O}_4$ /graphene composites prepared at different temperatures and that of the  $\text{Fe}_3\text{O}_4$  nanoparticles. As can be seen, the isotherms of the  $\text{Fe}_3\text{O}_4$ /graphene composites showed very obvious hysteresis loops and capillary condensation steps (Fig. 7(a) and (b)), suggesting the existence of porous structure in them.<sup>39</sup> In comparison with the composites,  $\text{Fe}_3\text{O}_4$  nanoparticles showed a narrow and irregular hysteresis loop and the capillary condensation steps shifted to a higher relative pressure, implying a reduction of porosity.<sup>40</sup> The BJH pore size distributions at around 39 nm and 38 nm, respectively, for  $\text{Fe}_3\text{O}_4$ /graphene ( $280^\circ\text{C}$ ) and  $\text{Fe}_3\text{O}_4$ /graphene ( $230^\circ\text{C}$ ) composites were calculated. But no uniform pore size in the pristine  $\text{Fe}_3\text{O}_4$  nanoparticles can be detected. The pore size distribution data of the samples, which were calculated from the desorption branch of the isotherms using the BJH algorithm, further supported the speculation deduced from the isothermal curve analysis. The pores in the  $\text{Fe}_3\text{O}_4$ /graphene composite could alleviate the volume changes of the  $\text{Fe}_3\text{O}_4$  nanoparticles during the lithium ion insertion/desertion process, which would lead to stable electrochemical performance (see Section 3.7). The calculated BET specific surface areas are 30, 19 and  $10\text{ m}^2\text{ g}^{-1}$ , respectively, for the above mentioned three samples. The large specific surface area of the  $\text{Fe}_3\text{O}_4$ /graphene ( $280^\circ\text{C}$ ) composite can be attributed to the integration of graphene sheets with the nano-sized  $\text{Fe}_3\text{O}_4$  particles. The increase of specific surface area for the  $\text{Fe}_3\text{O}_4$ /graphene composite prepared at high temperatures can be attributed to the difference of particle size. The smaller the particles sizes, the higher specific surface area could be deduced. The  $\text{N}_2$  adsorption–desorption measurements are consistent with the SEM and TEM observations (see Section 3.3).

### 3.7. Electrochemical properties

Fig. 8(A) shows the initial charge–discharge voltage profiles of the  $\text{Fe}_3\text{O}_4$ /graphene ( $280^\circ\text{C}$ ) composite and  $\text{Fe}_3\text{O}_4$

nanoparticles at 0.1 C ( $92.6 \text{ mA g}^{-1}$ ). The first discharge voltage profile of the  $\text{Fe}_3\text{O}_4/\text{graphene}$  composite is very similar to that of  $\text{Fe}_3\text{O}_4$  nanoparticles. Both of them presented a steep voltage drop from about 2.5 to 0.85 V, which can be attributed to the reaction of  $\text{Fe}_3\text{O}_4 + x\text{Li}^+ + xe^- \leftrightarrow \text{Li}_x\text{Fe}_3\text{O}_4$ .<sup>41</sup> Then the  $\text{Fe}_3\text{O}_4/\text{graphene}$  composite electrode showed a long discharge plateau potential around 0.85 V, which is due to the reduction of Fe ions to form nano-sized metallic Fe and amorphous  $\text{Li}_2\text{O}$  through a conversion reaction.<sup>42</sup> The sloping curve of the  $\text{Fe}_3\text{O}_4/\text{graphene}$  composite from about 0.83 to 0.01 V could be attributed to the formation of a solid electrolyte interface (SEI) film and the reversible reaction between lithium and graphene sheets  $2\text{C} + \text{Li}^+ + e^- \leftrightarrow \text{LiC}_2$ .<sup>43–45</sup> The initial discharge and charge capacities of the  $\text{Fe}_3\text{O}_4/\text{graphene}$  composites were estimated to be 1266 and  $897 \text{ mA h g}^{-1}$ , respectively, which are higher than those of the electrode made of pristine  $\text{Fe}_3\text{O}_4$  nanoparticles (978.5 and  $697 \text{ mA h g}^{-1}$ ). Fig. 8(B) shows the 1<sup>st</sup>, 2<sup>nd</sup> and 65<sup>th</sup> discharge–charge profiles of an electrode made of  $\text{Fe}_3\text{O}_4/\text{graphene}$  ( $280^\circ\text{C}$ ) composite at 0.1 C. A reversible capacity of  $907 \text{ mA h g}^{-1}$  was retained at 0.1 C even after 65 discharge–charge cycles. This confirms that graphene with outstanding intrinsic properties can effectively improve the electrochemical performance of transition metal oxides.

Fig. 9 shows the reversible capacity *versus* cycle number for  $\text{Fe}_3\text{O}_4$  nanoparticles and  $\text{Fe}_3\text{O}_4/\text{graphene}$  composites prepared at different temperatures. The reversible capacity of pristine  $\text{Fe}_3\text{O}_4$  nanoparticles faded quickly and showed a low capacity of only  $346 \text{ mA h g}^{-1}$  after 65 cycles (Fig. 9A). For the  $\text{Fe}_3\text{O}_4/\text{graphene}$  composites, it can be seen that with the increase of treatment temperature, the reversible capacities had obviously increased values. For the resultant composites at 230, 250 and  $280^\circ\text{C}$ , capacities of about 378, 781 and  $907 \text{ mA h g}^{-1}$ , respectively, were retained after 65 charge–discharge cycles. Their coulombic efficiencies remained more than 95%. On increasing the treatment temperature further to  $310^\circ\text{C}$ , no obvious improvement to the electrochemical performance of the resultant composite was observed. Therefore,  $280^\circ\text{C}$  has been selected as the preferred treatment temperature based on energy consumption considerations. The control  $\text{Fe}_3\text{O}_4/\text{graphene}$  composite prepared by the conventional solvothermal method, exhibited a low capacity of  $230 \text{ mA h g}^{-1}$  after 65 cycles, which is much lower than that delivered by the  $\text{Fe}_3\text{O}_4/\text{graphene}$  composites prepared *via* the high-temperature solvothermal processes and is even lower than that of the pristine  $\text{Fe}_3\text{O}_4$  nanoparticles ( $280^\circ\text{C}$ ). The theoretical weight percentage of the integrated graphene in our case is 7.4%, which is much lower than the reported data and will be of benefit to the commercialization of the  $\text{Fe}_3\text{O}_4/\text{graphene}$  composite.<sup>17,19,27</sup> There are several cycles showing capacity higher than the theoretical one, which may be due to the  $\text{Li}^+$  trapped both in the interlayer of carbons and cavities, as proposed by Tokumitsu *et al.*<sup>46</sup> The excellent capacity retention can be ascribed to the existence of graphene in the composites that can improve the electrical conductivity of the composite and can also accommodate the volume change of  $\text{Fe}_3\text{O}_4$  nanoparticles during the repetitive  $\text{Li}^+$  insertion–extraction cycling.<sup>47,48</sup> The capacity variation among the different composites can be contributed to by the

differences of morphology, particle size and crystal perfection of the  $\text{Fe}_3\text{O}_4$  particles in them derived at different temperature by the solvothermal synthesis. The remarkable high-rate capability of  $\text{Fe}_3\text{O}_4/\text{graphene}$  ( $280^\circ\text{C}$ ) is demonstrated in Fig. 9F. And reversible capacities of about  $830 \text{ mA h g}^{-1}$  at 0.1 C,  $720 \text{ mA h g}^{-1}$  at 0.2 C,  $615 \text{ mA h g}^{-1}$  at 0.5 C,  $540 \text{ mA h g}^{-1}$  at 1 C and  $410 \text{ mA h g}^{-1}$  at 2 C were delivered by this composite electrode. The reversible capacity returned to its original value as the current rate reduces back, revealing the superior reversibility of this composite electrode and its suitability as a high rate anode material.

To illustrate further the differences between  $\text{Fe}_3\text{O}_4$  nanoparticles and  $\text{Fe}_3\text{O}_4/\text{graphene}$  ( $280^\circ\text{C}$ ) composite, electrochemical impedance spectroscopy (EIS) measurements were carried out based on electrodes made of them in the frequency range from  $10^5$  to 0.01 Hz before or after testing the galvanostatic cycles, and typical Nyquist plots are given in Fig. 10. The EIS was also simulated by Z-view software using the equivalent circuit as shown in Fig. 10. In the equivalent circuit (inset),  $R_\Omega$  and  $R_{ct}$  are the ohmic resistance (total resistance of the electrolyte, separator, and electrical contacts) and the charge transfer resistance, respectively. CPE is the constant phase element and represents double layer capacitance, and  $W$  represents the Warburg impedance, reflecting the solid-state diffusion of Li ions into the bulk of the active materials. The Nyquist plots for the samples before and after cycling are similar, displaying a depressed semicircle in the high-middle frequency region, which could be assigned to the charge transfer resistance ( $R_{ct}$ ), and an inclined line in the low frequency region, which represents the Warburg impedance.<sup>49,50</sup> It can be seen from the image that the diameter of the semicircle for  $\text{Fe}_3\text{O}_4/\text{graphene}$  ( $280^\circ\text{C}$ ) before the cycle is much smaller than that of  $\text{Fe}_3\text{O}_4$  nanoparticles, indicating a lower charge transfer resistance of the material.<sup>51</sup> It is believed that the graphene existing in the system was responsible for the lower charge transfer resistance of the composite material. After 65 cycles, it is worth noting that the diameter of the semicircles was enlarged for both the samples. However, the lowest charge-transfer resistance was obtained again on  $\text{Fe}_3\text{O}_4/\text{graphene}$  electrode. The results confirmed that the existence of graphene significantly enhanced the conductivity of the electrode made of  $\text{Fe}_3\text{O}_4/\text{graphene}$  composite.

The cyclic voltammogram (CV) of the as-synthesized  $\text{Fe}_3\text{O}_4/\text{graphene}$  ( $280^\circ\text{C}$ ) composite was collected over the potential range from 0.01 to 3.0 V at a scan rate of  $0.1 \text{ mV s}^{-1}$ . As shown in Fig. 11(A) in the first cycle two peaks at 0.01 and 0.49 V, respectively, were observed for the cathodic process, which are ascribed to the lithiation reaction of  $\text{Fe}_3\text{O}_4 + 8\text{Li}^+ + 8e^- \leftrightarrow 3\text{Fe}^0 + 4\text{Li}_2\text{O}$  and  $2\text{C} + \text{Li}^+ + e^- \leftrightarrow \text{LiC}_2$ .<sup>52</sup> While two peaks at about 1.68 and 1.89 V were recorded in the anodic process, which correspond to the oxidation of  $\text{Fe}^0$  to  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  during the anodic process. During the subsequent cycles, both the cathodic and anodic peak potentials shift to high voltage ranges due to the polarization of electrode materials in the first cycle and the formation of the SEI film. Thereafter, the peak intensity tended to a constant and kept stable finally, implying good cycling stability. On the contrary, as shown in Fig. 11(B), the peak

intensity and integral areas of the CV curves in the first three cycles decreased obviously for Fe<sub>3</sub>O<sub>4</sub> nanoparticles, implying poor capacity retention ability. The results are also agreed well with the constant current discharge and charge processes testing.

## 4. Conclusions

Fe<sub>3</sub>O<sub>4</sub>/graphene composite anode materials with excellent electrochemical properties have been prepared by the one-step solvothermal method at elevated temperature (up to 310 °C) using an organic iron salt as precursor. On increasing the treatment temperature from 230 to 280 °C, the morphologies of the resultant Fe<sub>3</sub>O<sub>4</sub> particles turned from tubes with lengths of about 2 micrometers and diameters of about 300 nm to nanoparticles with diameters in range of 30–50 nm. In comparison with the traditional solvothermal method (<240 °C), the high-temperature one can provide Fe<sub>3</sub>O<sub>4</sub> nanocrystals in a short treatment time (only 6 h), meanwhile, the resultant Fe<sub>3</sub>O<sub>4</sub>/graphene composite could deliver higher capacity and better cycling performance than that derived from the traditional solvothermal process. Control experiments revealed that the Fe<sub>3</sub>O<sub>4</sub>/graphene composites prepared at 280 °C possessed the best electrochemical performance, and a high capacity of 907 mA h g<sup>-1</sup> could be retained after 65 cycles at a current density of 0.1 C (92.6 mA g<sup>-1</sup>). This strategy which employs graphene (<10% weight percentages) as supporting sheets for loaded metal oxide achieved by the one-step high-temperature solvothermal process was demonstrated to be an effective way to improve the specific capacity and the cycling performance of metal oxide anode materials for lithium ion batteries. The excellent electrochemical performance of the Fe<sub>3</sub>O<sub>4</sub>/graphene composites resulting from the high-temperature solvothermal process can be related to the enhancement of conductivity by the graphene sheets and the nano-scaled crystalline Fe<sub>3</sub>O<sub>4</sub> particles. The high temperature could result in Fe<sub>3</sub>O<sub>4</sub> nanocrystals with more perfect structure and enhance the important interfacial interaction between the graphene substrate and the Fe<sub>3</sub>O<sub>4</sub> nanocrystals (30–50 nm). Furthermore, the graphene substrates distributed among the Fe<sub>3</sub>O<sub>4</sub> nanoparticles can prevent the aggregation of the Fe<sub>3</sub>O<sub>4</sub> particles and can also provide a void against the volume changes of Fe<sub>3</sub>O<sub>4</sub> nanoparticles during the charge–discharge process. This high-temperature solvothermal method does not need a long reaction time and separate calcinations as usually required in the traditional method. This constitutes a facile approach to the synthesis of transition metal oxide/graphene composites with good cycling performance and high capacity retention as anode materials for lithium-ion batteries. We expect that the methodology presented herein will be also useful for the preparation of other kinds of electrode materials for LIBs.
